Reflective AI Feedback for Personal Productivity

Saidamir Osimov

April 9, 2026

1 Introduction

Productivity systems are everywhere.They have become deeply embedded in the daily life of millions of people, whether they work in the office, schools, or a project. They help maintain consistency and track tasks and goals. By reviewing someone's schedule and task list in their productivity app, you can learn a great deal about them, such as how busy they are throughout the week, how productive they are each day, and how many meetings and tasks they have. Task managers, digital planners, goal tracking dashboards, and habit-building apps: users now have multiple tools to organize their life and structure their time. All these platforms are great at dividing the work into actionable small steps, setting deadlines and monitoring completion rates across different horizons. While they are great at tracking and supporting execution, they rarely foster insight. Users can rigorously record what they do, but they receive little to no support in understanding how they work.

At the rate of tasks and pressure of commitments, individuals face cognitive overload. When tasks are completed, postponed, or rescheduled, it is often done so without any coherent decision-making behind them. Productivity tools generate data about the person more than ever before, but they provide minimal awareness about behavioral patterns, motivational cycles, or attention shifts. Tracking an activity is not the same as understanding it. Without systems for reflection, productivity tools are more like sophisticated record keepers rather than instruments for self-improvement.

1.1 The Need for Reflective Feedback

Reflection plays an important role in cognitive growth and sustained performance. Research in the field of cognitive science consistently shows that individuals improve not just by completing tasks, but by investigating how and why they approach them. In particular, a 2025 study, "Effect of feedback-integrated reflection on deep learning of medical students" [3], found that combining structured reflection with feedback caused significantly higher learning gains (approximately 69% compared to 29%). The study also highlights how reflective feedback reinforces metacognitive activity, enabling learners to monitor thinking and adjust behaviors effectively. When individuals look back and analyze patterns in their performance and attention, they develop awareness that supports more goal-aligned action.

Although, reflective practice is widely supported by research, most productivity platforms remain focused on task completion and execution rather than metacognitive development(awareness and understanding of your own thought process). Although users can record activities and track results, they are rarely encouraged to analyze their patterns or get personalized feedback. The absence of smart reflection systems shows a major disconnect between what cognitive science knows and what productivity tools actually offer.

Recent progress in artificial intelligence(AI), particularly large language models(LLMs) allow productivity systems to go beyond task management, toward cognitive support. Unlike traditional software, artificial intelligence can analyze large volumes of data and detect patterns across time and interpret contextual details in user generated logs. This allows the system to make sense of information rather than just collecting it. Large language models are capable of identifying recurring themes in work behavior, demonstrating inconsistencies between stated goals and actual actions, and generating reflection feedback in natural language. Artificial intelligence can help users to interpret their own patterns of focus, procrastination, prioritization, and energy allocation. In this sense artificial intelligence functions as a mechanism for cognitive augmentation. By letting intelligent systems handle pattern recognition and reflection, users can develop self-awareness without having to do all the mental heavy lifting themselves.

1.2 Introducing Newton

Newton is a productivity system designed to have artificial intelligence driven reflective feedback directly into the everyday workflow management. Built on top of the Supermind Design concept introduced by MIT[1], the platform encourages creative thinking and intentional execution rather than passive task tracking. The core functionality of Newton lies in its analysis of user activity through structured change logs. As users edit tasks, mark them complete and update goals, these changes are then captured and interpreted by an integrated artificial intelligence component. The system analyzes the logs to detect recurring patterns and inconsistencies. Based on this analysis, Newton generates personalized reflective insights that help users to zoom out of the daily routine and evaluate how their actions are aligned with their long-term goals. Rather than simply reporting what has been completed, the system highlights how your work develops over time and where you might need to adjust. This project explores how integrating AI-generated reflective feedback into productivity systems can enhance user awareness, improve workflow efficiency, and support more intentional decision-making.

2 Background

The Supermind Design method is humans and computers working together to generate better solutions to solve problems. Rather than replacing human thinking, these systems combine human creativity and judgement with computational power of the machines. Also, the Supermind Design is an approach to problem solving that combines big picture thinking with creative and intentional actions. Rather than focusing on isolated tasks, this method encourages individuals to view components to treat problems as parts of a larger, connected

whole rather than standalone issues to fix. A key part of this approach is looking at things from different angles, and considering both the small details and the bigger picture before making any decisions. By stepping back before diving into the details users can better spot root problems, and hidden issues that might be missed with a narrow focus. Supermind Design also promotes iterative reflection rather than strictly following a plan. Reframing plays a key role in this method, encouraging users to question assumptions and find alternative solution paths. This framework blends human intuition with structured reasoning.

2.1 Supermind Design in Newton

Newton applies the Supermind Design principles by combining human decision making with artificial intelligence generated insights. Instead of operating only as a task manager the system is designed to support the collaboration between the user and the artificial intelligence systems, that give reflective feedback and analyze the behavioral patterns. By analyzing the logs, the artificial intelligence component is able to help users see the patterns over time in their day-to-day work. This is the reflection of Supermind Design: combining humans with computational analysis to get better insights on productivity and workflow.

Artificial intelligence does not replace humans; it enhances them. The invention of the calculator did not replace the need for mathematicians, or math ability; it sped it up. An LLM does not replace thinking; it improves and supports reasoning. Newton is not doing the work for the user, it is helping them see the patterns in their own behavior and empowering them to look at their workflow from another perspective. That is augmentation. Artificial intelligence expands cognitive capacity.

A tool waits for the instructions, Newton is more like a partner that: 1) Observes 2) Suggests 3) Reflects. Traditional productivity apps are passive, Newton on the other hand is reflective. That is the difference. If I ask Siri a question, then it will give me an answer. I use Newton, it analyzes my behavior through the progress logs and tells me: "You tend to overcommit midweek" or "You abandon long-term tasks after 5 days".(Conclusion)

3 Related Works

Researchers have intensely studied how artificial intelligence systems can support task management and everyday work activities. Work by D. Trippas and colleagues [5] categorizes common workplace tasks to help design intelligent assistants that better understand the goals of the users and their activities. The study demonstrates that there are common patterns in work activities and tasks. Most commonly they involve multiple step tasks, goals and contextual factors. Other research [2] on future digital assistants in the workplace suggests that users want tools that are not just reactive tools but also adaptive supporters of complex work processes. Traditional digital assistants respond to commands and perform tasks. However, these studies indicate that the workers increasingly expect the assistants to understand context and support planning and decision making. On the same topic, Newton analyzes user task history and change logs to generate reflective feedbacks. Instead of simply following the commands, it aims to help users understand the patterns in their workflow and support

them in more informed decision making.

Recent research frames artificial intelligence as a tool for augmented human cognition, rather than replacing human decision making. This means that, artificial intelligence is used to help humans think better and support them in decision making. For example, Supermind Ideator developed by Thomas W. Malone and collaborators [1] showcases how structured human and artificial intelligence collaboration can improve creative problem solving. By offering support such as rephrasing problems, prompting new ideas, and guiding collaboration, the system helped users come up with significantly more creative ideas than when working alone or using regular AI tools. Similarly, research on the ExtendAI framework by Leon Reicherts and colleagues [4] shows that

AI systems are more effective when they extend and support users' reasoning processes rather than simply providing recommendations. Their findings suggest that AI tools that integrate with users' own decision-making strategies lead to better engagement and slightly improved outcomes. Research by Xiaotong Xu [6] also shows that adding AI to creative workflows can help users generate more ideas and explore problems more deeply.

Together, these studies point to a bigger shift in how artificial intelligence systems are being designed. The goal is always to support human thinking, not replace it. Newton takes this same approach by integrating AI into everyday productivity workflows, using data and task history to help users reflect on and improve their work habits.

4 Methodology

Newton is developed as a reflective productivity system that tracks not only what users accomplish, but also how they accomplish it over time. Instead of being a typical task manager that prioritizes execution and completion, Newton is more focused on pattern recognition and behavioral analysis. This is done to shift the usual task tracking toward deeper self-awareness. The system analyzes user activity, aiming to help individuals understand their habits, inconsistencies between planned goals and actual behavior, and decision-making. Artificial intelligence in Newton is used as a form of cognitive augmentation, helping users understand the information about their own workflow that would otherwise be difficult to track manually over time. By showcasing behavioral patterns and providing reflective feedback to users, Newton encourages them to step back and evaluate their work and make more intentional decisions on how to spend energy and time on tasks more efficiently.

A key feature of Newton's approach lies in its ability to record any change made in the platform regarding tasks and user activity over time. The system continuously logs any changes made in the platform in the Progress panel. These changes include events such as task creation, task completion, deletion, rescheduling, and edits along with their timestamps. Instead of treating each task as a single isolated action, these logs create a continuous record of how a user behaves and interacts with their own workflow, reflecting the real behavior. For instance, if a user frequently reschedules a task, it may be an indicator of overcommitment. Similarly, repeated edits may suggest uncertainty or shifting priorities. By collecting this information about the user, Newton is able to go beyond simple tracking and begin identifying behavioral patterns. This provides a foundation for generating reflective insights for users to better understand how they perform over time.

To turn raw activity logs into meaningful insights, Newton uses a large language model to interpret the behavior. The system provides the model with the change logs and a prompt that frames the task as reflective rather than directive. The prompt encourages the model to analyze the patterns in the behavior of the user, along with inconsistencies and trends. Depending on the implementation, this model may be deployed locally or accessed through an external API, with each option presenting trade-offs in terms of privacy, cost, and performance. Instead of just summarizing the data, the goal is to help the user be more aware of their workflow and behavioral trends, such as overcommitment, delays in task completion, and shifts in priorities.

The output is shown to the user in the form of structured feedback, organized as bullet points for readability. The insights are personalized and are directly related to the user's recent activity on Newton, making them more relevant. For instance, the system might highlight uneven workload distribution across the week, or inconsistencies between the stated goals and the accomplished goals. The system intentionally avoids giving instructions, instead providing reflective feedback that encourages the user to interpret and respond based on their own judgement. This reinforces the role of Newton as a cognitive supporter rather than augmenter. By presenting the feedback in a clear format, we help the user to quickly grasp the patterns in their behavior, avoiding the need for manual analysis.

5 Implementation

Newton is built as a web-application that combines the UI with the AI analysis tool. The system collects and stores user interactions locally using browser storage. Actions such as creating, editing, completing, or rescheduling tasks are recorded and used as the primary data source. When enough activity is collected, it is passed to a language model, which identifies patterns and generates reflective feedback. This creates a straightforward pipeline: raw interaction data is logged, analyzed, and returned to the user as meaningful insights.

The interface design of Newton is inspired by the Timestripe productivity application, infinite horizontal timeline feature in particular. Users can scroll infinitely to the left to view past days and to the right to plan future tasks, with each day represented as a column. Tasks are organized within these day columns, allowing users to visually structure their workflow over time. The application is composed of several key components, including a Sidebar for navigation, a Horizon panel 1 for task planning, a Progress panel 2 for viewing activity logs, and an AI Insights panel 3 for reflective feedback. The Horizon panel allows users to create and manage tasks across different dates, while the Progress panel records and organizes all changes made within the system. The AI Insights panel then presents the generated reflections based on this data. Together, these components create a continuous loop where user actions are recorded, analyzed, and reflected back in a way that supports awareness and adjustment.

From the implementation perspective, the system is structured using a component-based architecture in React. The main application initializes the interface and manages state, including storing tasks as date-keyed objects and maintaining change logs. Components such as DayColumn and TaskItem handle task-level interactions, while the TaskModal provides a more detailed editing interface. Data persistence is handled through local storage,

allowing user activity to be retained across sessions without requiring a backend. For the AI component, the current implementation uses a locally deployed DeepSeek 7B model to generate insights. While this approach offers advantages in terms of privacy and control, it introduces latency, with response times of several minutes. Future iterations may explore external API-based models, such as ChatGPT, which could significantly reduce response time at the cost of reduced data locality and potential privacy considerations.

Newton extends the Horizon panel by introducing multiple time scales, including day, week, month, and year views. Each of these sub-panels operates on the same structural principle, where tasks are grouped into time-based columns, but they serve different planning purposes. This allows users to shift between short-term execution and long-term planning without changing the underlying interaction model. A key feature within each column is the ability to generate AI-driven insights directly from that specific time frame. By clicking an insight trigger within a column, the system collects completed tasks within that period and sends them to the language model for analysis. This enables localized reflection, where users can evaluate productivity at different temporal resolutions, such as understanding how a single day compares to a full week or month.

In addition to a default system prompt that frames the AI as a productivity coach, Newton allows users to customize the prompt used for generating insights 4. This design choice introduces flexibility and user control into the reflection process. While the default prompt focuses on general productivity patterns, users can modify it to emphasize specific goals, such as time management, focus, or consistency. At the same time, the system provides an option to reset to the original prompt, ensuring that users can always return to a stable baseline. This feature reflects an important design principle: reflection should not be imposed in a single rigid format, but instead adapted to individual preferences and needs. By allowing users to shape how the AI interprets their data, Newton moves closer to a personalized cognitive support system
